Hematopoietic Stem Cells

High number of circulating CD34+ cells in patients with myelophthisis

Six patients with bone marrow micrometastases from solid cancers presented with increased numbers of circulating CD34+ cells; the CD34+ cell counts were very high in some cases. By contrast, no patient with metastatic cancer without bone marrow involvement showed raised numbers of circulating hemopoietic progenitors.

The circulating CD34 (cCD34+) cell count is assessed daily to monitor stem cell mobilization in patients undergoing stem cell harvest from peripheral blood. Another condition with raised numbers of cCD34+ cells is idiopathic myelofibrosis, a finding suggesting that a normal bone marrow microenvironment is essential for the binding of CD34+ cells to stroma. Myelophthisis is a peculiar bone marrow microenvironment alteration caused by the presence of a high number of non-hematopoietic neoplastic cells, impairing hematopoiesis by largely unknown mechanisms. Space occupation is not the main mechanism, since micrometastases do not colonize the whole marrow; rather, marrow is usually hypocellular, with some degree of fibrosis revealed at bone biopsy. We investigated the number of cCD34+ cells in patients with myelophthisis.

We studied eleven patients with diffuse metastatic cancer (Table 1). Myelophthisis was suspected in patients presenting uni-, bi-, or trilineage cytopenia not due to chemotherapy, and was documented by the finding of non-hematopoietic neoplastic cells in a bone marrow aspirate and/or biopsy. Peripheral blood, collected in KEDTA, was processed within 3 hours of venipuncture. CD34+ cells were detected by a combination of two monoclonal antibodies, fluorescein isothiocyanate-conjugated anti-CD45 and phycoerythrin-conjugated anti-CD34 (Becton Dickinson, Boston, MA, USA); c-kit expression was also measured. Fifty microliters of blood were incubated with the antibodies for 20 min in tubes containing a known number of microbeads. Cells were identified by FACSCalibur (Becton Dickinson, Boston, MA, USA) using scattering and fluorescence methods, and analyzed following the sequential gating strategy recommended by the International Society for Hematothepathy and Graft Engineering (ISHAGE). To exclude any influence of drugs, patients were studied before or at least three months after chemotherapy; none of the patients had received growth factors.

Of the eleven patients with metastatic cancer of various origin, six showed bone marrow micrometastases, suggested by cytopenia and documented by bone aspirate and/or biopsy, while five patients had no sign of bone marrow involvement. Marrow fibrosis (surrounding the metastatic lesions) was detected in the three patients with myelophthisis who underwent bone biopsy. cCD34+ (c-kit+) cell counts were elevated in all 6 patients with myelophthisis, and were particularly high in four. In contrast, CD34+ cells were almost undetectable in the patients with metastatic cancer without bone marrow involvement (Table 1). The mean number of cCD34+ cells was 49.2 and 1.2 cells/μL in the two groups, respectively. Among patients suffering from various types of disorders and tested for cCD34+ cells in our institution, the number of cells detected was second highest in myelophthisis; the highest number was found in idiopathic myelofibrosis (Figure 1).

Stem cell mobilization by growth factors and/or chemotherapy is caused by modifications of membrane-bound molecules that enable detachment of cells from the stroma. The only disease in which a high number of cCD34+ cells has been described in the absence of any treatment is idiopathic myelofibrosis, both an altered bone marrow microenvironment and stem cell surface

*: low count due to hypersplenism secondary to hepatitis C virus-related chronic hepatitis.
abnormalities may underlie this phenomenon. A modest increase of cCD34+ cells, attributed to granulocyte-monocyte colony-stimulating factor (GM-CSF) production by the neoplastic tissue, has been described in patients with head or neck cancer.⁶ We found that patients harboring cancer cells in the bone marrow had a mean of 49.2 cCD34+ cells/μL, 50 times more than in patients with metastatic cancer without bone marrow involvement. This may be the consequence of various not mutually exclusive mechanisms, including: (i) a stromal alteration, evidenced in these patients by a frequent dry tap bone marrow aspiration and some degree of fibrosis;⁵ (ii) growth factors with mobilizing properties produced locally by the neoplastic cells; (iii) local production of molecules other than growth factors involved in stem cell mobilization. As far as concerns this last possibility, it could be relevant to note that a cleaved molecule of soluble urokinase-type plasminogen activator (uPA) receptor (uPAR) expression in cancer.⁷

Our series is too small to draw any conclusion on a possible relation between degree of cytopenia and number of cCD34+ cells; the type of primary tumor does not seem to be relevant. It is intriguing that two patients with raised cCD34+ cell counts had low hemoglobin and platelet levels but elevated neutrophil counts, suggesting a common mechanisms for high cCD34+ and white cell counts, as seen during mobilization. Several issues in this setting need to be elucidated (e.g., cytokine levels in blood and bone marrow, pattern of adhesion molecules and in vitro growth of cCD34+ cells). From a clinical point of view, our observations suggest that high cCD34+ cell count may be indicative of bone marrow involvement in patients with metastatic cancer.

Red Cell Disorders

Association of the G-463A myeloperoxidase polymorphism with infection in sickle cell anemia

Infections constitute a principal cause of morbidity and mortality in sickle cell anemia (SCA). Here we present evidence to suggest that a polymorphism (G-463A MPO) in the gene encoding the myeloperoxidase (MPO) enzyme, important for the host defense system, may significantly increase susceptibility to infection in SCA.

haematologica 2005; 90:977-979
(http://www.haematologica.org/journal/2005/7/977.html)

Sickle cell anemia is characterized by morphologically abnormal red cells, vaso-occlusion with ischemic tissue injury and susceptibility to infection. Infections, such as pneumonia, osteomyelitis, meningitis, urinary infections and septicemia, constitute a common cause of hospitalization in patients. While many patients have reduced splenic function, the mechanisms that render SCA patients more susceptible to infection are unclear. The severity of SCA varies greatly between individuals and this phenotypic variability is generally attributed to so-called genetic modulators. Myeloperoxidase (MPO) is a lysosomal enzyme found in neutrophils and monocytes
