Publisher's Disclaimer.
E-publishing ahead of print is increasingly important for the rapid dissemination of science. Haematologica is, therefore, E-publishing PDF files of an early version of manuscripts that have completed a regular peer review and have been accepted for publication. E-publishing of this PDF file has been approved by the authors. After having E-published Ahead of Print, manuscripts will then undergo technical and English editing, typesetting, proof correction and be presented for the authors' final approval; the final version of the manuscript will then appear in print on a regular issue of the journal. All legal disclaimers that apply to the journal also pertain to this production process.

Disclosures:
IBS has served as a consultant for or received honoraria from Sanofi, Abbvie, Amgen, OPKD Health, and Keryx Biopharmaceuticals. EN and TG are shareholders of Intrinsic LifeSciences, a company developing hepcidin diagnostics; Merganser Biotech, a company developing hepcidin-based therapeutics; and Silarus Therapeutics, a company developing erythroferrone-based therapies. TG has also served as a consultant for Keryx Biopharmaceuticals.

Running Title:
Hepcidin contributes to CKD-associated anemia

Word Count:
Abstract: n/a
Main text: 1334
Figures: 3
Tables: 0
Supplemental files: 0
Anemia is very common in chronic kidney disease (CKD) patients (1), and has been associated with adverse cardiovascular outcomes in this population (2). The pathogenesis of CKD-associated anemia is multifactorial, contributed to by relative erythropoietin (Epo) deficiency, absolute and functional iron deficiencies, decreased red blood cell survival, and uremia-induced erythropoiesis inhibition (3). The iron-regulatory hormone hepcidin may provide a link between inflammation and disordered iron homeostasis that contributes to CKD-associated anemia. Moreover, hepcidin-mediated iron restriction may contribute to resistance to recombinant Epo (4), one of the mainstays of CKD-associated anemia treatment. Epo hyporesponsiveness and the utilization of high-dose Epo have been associated with increased mortality rates in the CKD population (5). As such, possible therapies targeting hepcidin may result in improved Epo responsiveness and improved outcomes. Therefore, elucidation of the role of hepcidin in CKD may allow for a better understanding of the pathogenesis of CKD-associated anemia, as well as insight into optimal anemia treatment strategies in CKD patients.

Hepcidin is secreted by the liver, and regulates iron levels by binding to the cellular iron exporter ferroportin, causing its internalization and degradation, resulting in decreased iron export from cells into plasma (6). Hepcidin affects enterocytes, inhibiting dietary iron absorption; hepatocytes, preventing the mobilization of hepatic iron stores; and hepatic and splenic macrophages, inhibiting the efflux of recycled iron (6). Reticuloendothelial cell sequestration of iron results in a functional iron deficiency and an iron-restricted erythropoiesis. Hepcidin production is induced by iron loading and inflammatory cytokines, and suppressed by iron deficiency and erythropoietic activity (7).

Cross-sectional studies have shown that, as glomerular filtration rate declines, circulating hepcidin levels increase in CKD patients (8). Elevated hepcidin in CKD is thought to result from increased inflammation and/or decreased renal function, as kidney excretion represents a major
mode of hepcidin clearance (9). However, the assessment of hepcidin levels in CKD patients may be confounded by the use of erythropoietin-stimulating agents (ESA) and iron therapy, as both erythropoiesis and iron therapy affect hepcidin levels. Importantly, cross-sectional studies demonstrate only an association between increased hepcidin levels and worsening kidney function, without proving that hepcidin actually contributes to CKD-associated anemia. Furthermore, measurement of serum hepcidin levels in humans is not standardized, and different studies have utilized different assays, including ELISAs, radioimmunoassays, and mass spectrometry-based assays. As absolute hepcidin levels differ based on which assay is used (10), comparing hepcidin measurements among studies is difficult.

We sought to determine the role of hepcidin in CKD-associated anemia using a mouse model, which allowed us to circumvent possible confounding by ESA use and/or iron therapy. We compared hepcidin knockout (HKO) CKD mice to wild type (WT) CKD mice, allowing us to directly test the hypothesis that hepcidin ablation ameliorates CKD-associated anemia. CKD was induced in WT C57BL/6 mice (n=16) and HKO C57BL/6 mice (n=22) by feeding them a 0.2% adenine diet for eight weeks (11). Corresponding WT (n=16) and HKO (n=20) control groups were placed on identical diets without adenine. The study diets were started when the mice were eight weeks old. To prevent the development of iron overload, the HKO mice were fed a low iron diet containing 4 ppm iron from weaning at four weeks of age until study diet initiation. WT mice were fed standard mouse chow containing 335 ppm iron until study diet initiation. All study diets (adenine and no adenine) contained 50 ppm iron, a concentration which provided sufficient iron to the WT mice without overloading the HKO mice. Hematologic parameters were measured at diet initiation and at study conclusion.

After eight weeks of the adenine-rich diet, the WT CKD and HKO CKD groups had markedly higher blood urea nitrogen (BUN) levels than their control counterparts (Fig. 1a). In both the WT
CKD and HKO CKD groups, renal histology showed adenine crystals and marked tubulointerstitial damage with leukocytic infiltration, similar to what has been observed in other C57BL/6 mouse adenine-induced CKD models (11) (Fig. 2). In both the WT and HKO cohorts, levels of serum amyloid A (SAA), an inflammatory marker, did not differ between the Control and CKD groups at the study end point (Fig. 1b). Serum hepcidin levels were higher in the WT CKD group than in the WT Control group (Fig. 1c), and increased despite anemia, mimicking human CKD. In all WT mice, hepcidin positively correlated with BUN (Fig. 3a). In HKO mice, circulating hepcidin levels have previously been shown to be undetectable (12). The observations that the WT CKD group had higher hepcidin levels than the WT Control group despite similar SAA concentrations, and that hepcidin positively correlated with BUN, suggest that decreased hepcidin clearance may be important in this CKD model. Interestingly, serum iron increased in the WT CKD and HKO CKD groups (Fig. 1d). This increase in serum iron occurred despite elevated hepcidin levels and anemia in the WT CKD group, suggesting decreased consumption of iron, and less efficient use of iron for erythropoiesis, in the setting of CKD. Also, serum iron and hepcidin did not correlate, similar to what has been observed in human CKD studies (13).

Among the WT mice, the WT CKD group experienced marked decreases in mean corpuscular volume (MCV) and hemoglobin (Figs. 1e-f). In all WT mice, MCV and hemoglobin inversely correlated with hepcidin (Figs. 3b-c). The WT CKD group had only marginally higher serum erythropoietin levels than the WT Control group, and the levels remained unchanged from baseline (Fig. 1g, p=0.53 vs. baseline), indicating a failure to respond to anemia. In contrast to the WT CKD mice, the HKO CKD mice developed only slightly lower MCV and hemoglobin vs. Controls (Figs. 1e-f). Indeed, the development of CKD, with similar degrees of uremia, resulted in significantly greater anemia in the WT mice (hemoglobin ~6 g/dl lower than controls) vs. the HKO mice (hemoglobin ~2 g/dl lower than controls) (p=0.048), suggesting the pathogenic role of
hepcidin in the anemia of CKD. Compared to baseline values, hemoglobin remained unchanged in the HKO CKD group (p=0.99), but increased from baseline in the HKO Control group (p<0.001). This small increase in hemoglobin in the HKO Control group was likely due to the different diets that the HKO mice were fed prior to the baseline measurements (four weeks of 4 ppm iron diet) vs. the final measurements (eight weeks of 50 ppm iron diet), a regimen necessary to prevent iron overload in these mice. The higher iron content in the eight-week study diet allowed the HKO Control group to develop mild polycythemia, which is commonly observed in HKO mice (14). For the same reason, both the HKO Control and CKD groups had increased MCV (\textbf{Fig. 1e}) and decreased erythropoietin (\textbf{Fig. 1g}) compared to baseline (p<0.05 for both), although the differences were more pronounced in the HKO Control group. Also, the slightly lower hemoglobin and MCV in the HKO CKD mice vs. Controls suggest that other CKD-associated factors besides hepcidin affect erythropoiesis.

Nevertheless, in this murine CKD model, hepcidin ablation clearly ameliorated CKD-associated anemia, demonstrating the importance of hepcidin in this pathologic process. Similar results were recently published by Akchurin et al (15), demonstrating the reproducibility and robustness of this finding. The significant contribution of hepcidin to the anemia of CKD is an important observation given the potential of anti-hepcidin therapies as possible future treatments of CKD-associated anemia. Also, in the WT CKD group, we observed elevated hepcidin levels despite no difference in inflammatory markers, suggesting that impaired renal clearance may be an important determinant of hepcidin levels in CKD.

There are several limitations to our study, including incomplete biochemical assessment. Given the limited amount of blood available from each mouse, blood urea nitrogen was the only evaluation of renal function. Also, to assess iron status, we measured serum iron levels, but did not calculate transferrin saturation or quantitate hepatic iron content, the latter of which may
have provided a better estimation of total body iron stores. Still, in a mouse model unburdened by the limitations of human studies, we have demonstrated that serum hepcidin levels increase in CKD and significantly contribute to CKD-associated anemia.
